## Comparisons of infant mortality in the Austrian Empire *Länder* using the *Tafeln* (1851-54)

Fiorenzo Rossi<sup>2</sup>

### Abstract

In this paper we measure differences in infant mortality among the central European populations of the Austrian Empire during the mid-19th century using data published in the *Tafeln zur Statistik der Österreichischen Monarchie* (Statistical Tables of the Austrian Monarchy). Our aim is mainly methodological, i.e., to illustrate the extraordinary richness of this data, and to discuss whether the quality of the material on infant mortality published around 1850 in the *Tafeln* guarantees comparability between regions. This article demonstrates that – with several exceptions – the quality of the material on infant mortality published in the *Tafeln* around 1850 guarantees reliable comparability between the Empire's *Länder*. Data on sex, age at death, and legitimacy were all recorded with great accuracy. This article – of a methodological nature – provides only a few examples of potential analyses which might be carried out using such rich and detailed territorial data. The geography of mortality in the first three years of life varied by age, but according to intervals different than those usually employed when studying early mortality. Four ages can be identified (first month, months 1-5, months 6-17, and months 18-35) with a geography of differing mortality. In all likelihood, in these four age groups, mortality differences between *Länder* were motivated by diverse reasons.

## 1. Introduction

In this paper we measure differences in infant mortality among the central European populations of the Austrian Empire during the mid-19<sup>th</sup> century using data published in the *Tafeln zur Statistik der Österreichischen Monarchie* (Statistical Tables of the Austrian Monarchy). Our aim is mainly methodological, i.e., to illustrate the extraordinary richness of this data, and to discuss whether the quality of the material on infant mortality published around 1850 in the *Tafeln* guarantees comparability between regions. A brief premise concerning the meaning of such an analysis provides additional support for this important methodological investigation.

Over the last few decades, numerous studies have sought to explain historical differences in the risk of dying during the earliest stages of life (see, e.g., Vallin 1991; Lee 1991; Preston and Haines 1991; Bideau, Desjardins, and Pérez Brignoli 1997; Corsini and Viazzo 1997; Bengtsson, Campbell, and Lee 2004; Breschi and Pozzi 2004). Thus far, however, a complete comparative map of infant mortality for the regions of Europe from 1650-1900 is not available. Two important patterns remain less than fully explained. First, although the risk of dying during the first year of life during the *ancien régime* was everywhere higher than 100%, considerable differences existed between populations living in adjacent regions and countries (Livi Bacci 1997: point 2). Second, secular trends may have significantly varied between neighbouring populations (Livi Bacci 1997: point 6). Although these issues are not easily disentangled, they are crucial to understanding the historical determinants of infant mortality. The *Tafeln* are potentially an important source for examining infant mortality in the Austrian Empire during the first half of the 19<sup>th</sup> century, and for exploring the patterns mentioned above. In this paper, we focus on the first pattern, measuring differences in infant mortality among mid-19<sup>th</sup>-century *Länder* through use of published data in the *Tafeln*. The second issue will be analysed in the near future.<sup>3</sup>

The *Tafeln* include about 20 of the large Empire's *Länder* (regions), which during 1815-1861 were home to about 35 million people, and extended from Milan, now in Italy, to Ternopil, now in Ukraine (about 1,200 km West-East); and from Krakow, now in Poland, to Kotor, now in Montenegro (about 1,000 km North-South). This area was characterised by much orographic, climatic, cultural, religious, linguistic and economic

---

<sup>3</sup> This article represents the first product of a larger research project on the demographic exploitation of the *Tafeln zur Statistik der Österreichischen Monarchie*, funded by the Max Planck Institute for Demographic Research of Rostock (Germany). We thank all participants in the seminar held at the Max Plank Institute of Rostock in January 2009 – especially Joshua Goldstein and Chris Wilson – for their comments and suggestions. We also express our gratitude to the anonymous referees for their reactions and comments to the first draft of this paper.

diversity (Table 1 and Figure 1). On the other hand, given the common political (and centralistic) administration across the *Länder*, it is possible that data was collected following similar norms and procedures. With regard to several aspects concerning infant mortality this is only partially true, although territorial comparability indubitably remains better than in other *ancien régime* contexts. Moreover, the *Tafeln* are now available for the period of 1829-65, albeit with different details and territorial coverage. The latter include not only a plethora of demographic information, but also data on the economy and social life. Finally, several time series are long enough to allow for a comparison of temporal trends.

In the following section, we discuss the typology of the data and their quality (completeness, age-heaping, etc.). In the third section, we illustrate the methodology employed to build a life table for the first three years of age for the cohort born in 1851. Age at death is classified in months for the first three months of life, quarterly until the first birthday, bi-yearly until the second birthday, and then annually for the third year of life. For each region, it is possible to calculate life tables for these ages by sex and legitimacy. Data on stillbirths were also collected, although their quality seems relatively poor. The last sections are dedicated to a preliminary discussion of the differences in infant mortality among the Austrian Empire *Länder* during the mid-19<sup>th</sup> century.

## 2. Typology and quality of data

As mentioned above, the data come from a large collection of information known as the *Tafeln*. Published between 1829 and 1871 (referencing the period of 1828-65), the *Tafeln zur Statistik der Österreichischen Monarchie* represent an important stage in the history of public statistics. The evolution of the quantity and quality of the statistics is quite evident. Beginning with only a small office within the Accounting Governance Checks, the management of statistics later passed, in 1840, to the Statistical Administrative Directorate under the Presidium of the Accounting General Directorate; in 1848, it was moved again, this time directly under the Ministry of Commerce, Industry, and Public Works. The first edition contained 104 statistical tables addressing a variety of topics: territory and population, the economy, justice, schools, administration, etc. The 1846 edition (containing data collected in 1841) was renovated in part through the use of printed lead characters, which replaced the manual lithographic edition which preceded it. In addition, the data (with the exception of military and financial information) were made public; beginning in 1846, the *Tafeln* became available in many public libraries. In 1856, a new series was published, containing data from the period 1849-1856. Starting in 1860, the *Tafeln* came out every five years. The last edition was published in 1871, using data from 1860-1865. In the years that followed, the *Tafeln* were substituted by statistical yearbooks and periodical publications focusing on specific issues.

Data relative to the period of 1851-1854 are particularly rich and detailed. Of interest to this paper, births and deaths were recorded in terms of vitality, legitimacy, and sex (eight modalities in total). Death during the first three years of life was differentiated according to nine separate age classifications, as indicated above. Data are available for all of the *Länder*, with only a few exceptions (see Table 2).

Religious authorities (priests in the Catholic parishes, pastors in the Protestant parishes, rabbis in the Jewish communities, etc.) also served as *civil status officials*. In this capacity they were responsible, on behalf of the State, for updating the standardised and pre-printed registers of weddings, births, and deaths (which often mirrored those of religious nature). The *Tafeln* calculations are based upon the data contained in these civil registers.

Serious setbacks impeding access to reliable information arise for only three *Länder*. For *Oesterreich unter der Enns*, there are no data on deaths in Vienna for the years 1851 and 1852; births were reported separately for these years. We attempted to build mortality measures for this *Land*, with the exclusion of Vienna, for the years 1851 and 1852, but the results are somewhat suspect. Consequently, they are not considered in this paper. For *Dalmatien*, there are no data on deaths for any of the four years under consideration. For *Kroatien und Slavonien*, data on deaths are similarly lacking for the

first three years, while data on births are missing for 1851. Other shortages of data or discrepancies can be overcome. For example, data on both births and deaths for *Görz, Gradisca und Istrien* were published separately from *Triest sammt Gebiet* only in the year 1851; in this paper, we always combine them. For the following three *Länder*, *Lombardie*, *Venedig*, and *Serbische Wojwodschaft und Temeser Banat*, the number of births ( $B_{51}$ ) for 1851 was published, but not the number of deaths ( $D_{51}$ ). We thus estimated the latter, age by age, assuming the same infant mortality as that of 1852:  $D_{51}=D_{52}x(B_{51}/B_{52})$ . A check using the cohort of 1852, focusing on the first year of life, gave reassuring results. Finally, 1851 data for *Serbische Wojwodschaft und Temeser Banat* include only the total of live births and stillbirths. This distinction is estimated using the same proportion found among the 1852 births.

(\*) Data available by sex, legitimacy, and vitality ( $2 \times 2 \times 8$  categories).

(\*\*) Data available by sex, legitimacy, and age (in months for the first three months, quarterly until the fifth birthday, bi-yearly until the second birthday, annually for the third year of life ( $2 \times 2 \times 9 = 36$  categories)).

Other authors have considered the demographic balance for years adjacent to the census in order to check the consistency of births, deaths, and census counts (Findl 1979; Ediev and Gisser 2007:338). Those works indicated that there was good coverage of births and deaths, but a sort of “shortage” of infants in census counts for the Austrian *Alpenländer*. We assess the coverage of the recorded data on births and deaths without considering census data, but using some simple devices. One is to verify whether the sex ratio, taking into account the large scale of the observations, varies significantly from a ratio of 105-106 male births for every 100 female births. This ratio hardly differs across human populations, independent of space and time. Higher values indicate a tendency to ‘under-register’ female infants. For the years under consideration, we observe little more than 106 males for every 100 females, for a total of about 1.4 million live births registered every year (Table 3). In several cases, this value shifts away from the reference ratio, although this occurs predominantly in the relatively small populations. In the more populous regions (*Böhmen*, *Galizien*, *Ungern*), the sex ratio is quite close to 106.

The sex ratio at birth,  $100 \times M/F$ , looks like a normal random variable, distributed all around the mean of 106. Consequently, it is possible to calculate the 95% confidence-interval that depends only on the number of births (Livi Bacci 1999:25-26) – the greater the number of the births, the narrower the interval (Table 3). The sex ratios fall outside the interval only three times: *Krakau* in 1853 (about 6,000 births every year), *Dalmatien* in 1854 (about 13,000 births), and *Lombardie* (106,000) (Figure 2).

(\*) 1853 and 1854 Wien included.

(\*\*) In 1851 Görz, Gradisca und Istrien 104.9 with 15,135 births; Triest 104.5 with 4,219 births.

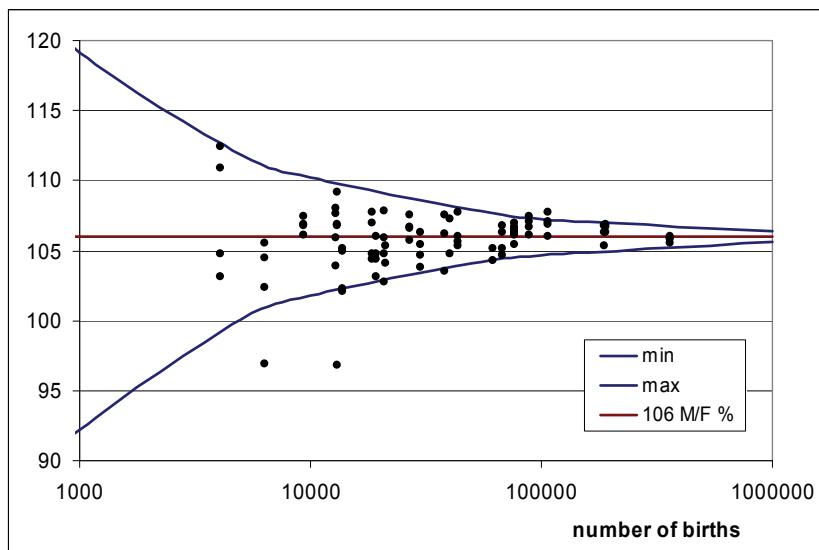

(\*\*\*) 1851 calculated on total live births and stillbirths.

(\*\*\*\*) 1852 and 1853 calculated on total live births and stillbirths (38,326 in 1852).

Different considerations arise with regard to the completeness and quality of the information on stillbirths (Table 4). The results indicate that stillbirths represented about 1.5% of total births (live births plus stillbirths), a low percentage when compared to countries with analogous levels of infant mortality. For example, in Italy the proportion of stillbirths was 2.2% in 1861-1870, 2.9% in 1871-1880, 3.5% in 1881-1890, and 4.0% in 1891-1900 (Istat 1976). During the same period, infant mortality dropped from 226‰ (1861-1870) to 176‰ (1891-1900). The large degree of variability

among *Länder* also suggests that the registering criteria were not entirely homogeneous. Nonetheless, understanding the direction of these differences is not simple given that – with the *Länder* considered as statistical units – the territorial correlation between stillbirths and mortality in the first month of life is next to zero. The sex ratio, on the other hand, is closer to ‘normal’ (136 male stillbirths for every 100 female stillbirths), and is similar to ratios seen in other contexts during this period (an average of 134 in Italy during 1861-1900, Istat 1976), as is the higher percentage of illegitimate infants among stillbirths (18.5%) than among live births (8.3%).

**Figure 2:** Sex ratio at birth ( $100 \times M/F$ ) by number of births and 95% confidence intervals. *Länder* of the Austrian Empire, 1851-54

Nominative surveys of this data for two parishes (Agna and Casalserugo), both located in the province of Padua (in *Venedig*), reveal that different criteria were employed for registering stillbirths during the period 1821-1866 (Dalla-Zuanna and Rosina 2008). In Agna, the priest recorded the deaths of unbaptised children as stillbirths. In Casalserugo, stillbirths were simply not recorded, and the number of baptisms in the canonical register is the same as the number of births in the civil register. Such differences suggest that caution should be used when considering this

sort of data. In constructing the life table, we chose not to consider stillbirths, and henceforth estimates of infant mortality indicators are based on live births.

**Table 4: Stillbirths: proportion and sex ratio.

(\*) 1853 and 1854 Wien included.

(\*\*) In 1851 Görz, Gradisca und Istrien 1.3; Triest 4.8.

In the *Tafeln*, births are systematically differentiated by legitimacy (Table 5). Variability between regions is substantial, ranging from over 50% illegitimate births in Vienna (this indicator decreases to 26% when considering the entire territory of *Oesterreich unter der Enns*), to only 1%-3% in several of the eastern and southern Austrian Empire *Länder* (*Dalmatien, Militärgränze, Serbische Wojwodschaft und Temeser Banat, Venedig*). Finally, in 1851, it is possible to observe the difference between *Triest* (21.9%) and its territory (*Görz, Gradisca, Istrien*: 2.6%); in the years that followed, however, the data are combined. The high levels observed in Vienna and Trieste may be related to the urban concentration of foundling institutes. More generally, the considerable differences between groups of *Länder* may be due to different legislation governing marriage. In places where the percentage of illegitimate births is systematically higher – for the most part, German-speaking *Länder* located in the area which, after 1918, became the Republic of Austria – there were strong legal restrictions on marriage for the poor (Prioux 1993; for *Tirol-Vorarlberg*, and mainly the county of Trento, see also Grandi 1995). With regard to legitimacy levels, three groups of *Länder* can be identified, revealing a certain degree of territorial continuity (Figure 3): high level of illegitimacy (20% or higher during 1851-1854): *Oesterreich unter der Enns, Oesterreich ob der Enns, Salzburg, Steiermark, and Kärnthen*; medium (5%-20%): *Krain, Görz Gradisca und Istrien Triest sammt Gebiet, Tirol und Vorarlberg, Böhmen, Mähren, Schlesien, Krakau sammt Gebiet, Galizien, and Bukovina*; and low (5% or lower): *Dalmatien, Lombardie, Venedig, Ungern, Serbische Woiwodschaft und Temeser Banat, Kroatiens und Slavonien, Siebenbürgen, and Militärgränze*.

**Table 5: Illegitimacy by vitality (% illegitimate births).**

(\*) 1853 and 1854 Wien included.

(\*\*) In 1851, respectively on live births and on still births: Görz, Gradisca und Istrien 2.6 and 5.0; Triest 21.9 and 37.2.

**Figure 3:** Illegitimacy in the *Länder* of Austrian Empire, mean 1851-54

With regard to deaths, one way of evaluating the quality of the registers is to examine the quota of death acts lacking any indication of age. For the period of 1851–1854, the *Tafeln* include the distribution of deaths by single annual ages for each *Land*, including additional details (as described above) for ages up to three. Death acts lacking any indication of age are quite rare: 0.11% in the period 1851–1854, when considering the Empire as a whole. Unknown to us, however, is whether this low level (so low as to raise some suspicion) can be linked to a corrective system applied to non-responses of age existent at the local or administrative level.

Another way of evaluating the quality of the data on deaths is to estimate any possible rounding of the age at death recorded on the act. As mentioned above, data on death during the first year of life in the *Tafeln* are classified by month for the first three months, and then by trimester for the ages that follow. It is, consequently, not possible to conduct a detailed analysis specific to the exact number of months. That said, several results from other studies concerning the first year of life should be mentioned. For example, Ediev (2003), in his work on 1897 Russia, observed a strong attraction to six months in the classification of children less than a year old by single month of age. A similar attraction to six months is present in several parishes of *Venedig* during the 17th and 18th centuries – albeit to a much lesser degree than is reported in Ediev's results. The attraction then progressively lessens and then disappears in the 19th century (Rossi and Tesolat 2006).

An additional consideration, useful when reflecting on the results in the infant mortality table, concerns age-heaping at several adult ages. Deaths by ages 5–94 in each of the *Länder* in the year 1852 were grouped according to the last digit: the frequency of each digit should not, therefore, be much more than 10% (Table 6 and Figure 4). Age-heaping at ages that end in 0 and 5, which is most commonly observed, is quite contained: it exceeds 13% in only one region for ages ending in 0, and in two regions for ages ending in 5, without any notable differences by sex. However, in a number of regions (*Schlesien*, *Krakau sammt Gebiet*, *Galizien*, *Bukovina*, *Ungern*, *Serbische Woiwodschaft und Temeser Banat*, *Siebenbürgen* and *Militärgränze*), there is an attraction to ages that end in 9 (with a frequency near or higher than 13%); in one region, the frequency is also slightly elevated for ages that end in 6. However, these minimally elevated percentages concern only the eastern regions of the Empire (death by age are not available for *Kroatien und Slavonien*). It is not easy to interpret the significance of this result in the absence of information both relative to criteria used when passing from single to aggregated data, and the criteria used in the age classification. In this specific case, there may be a classification issue concerning age at last birthday (complete years), as opposed to age at next birthday (years begun). In other words, in these regions the actual attraction could be on years begun, which end in 0 (for example, 30), then classified as complete years, which end in 9 (for example, 29).

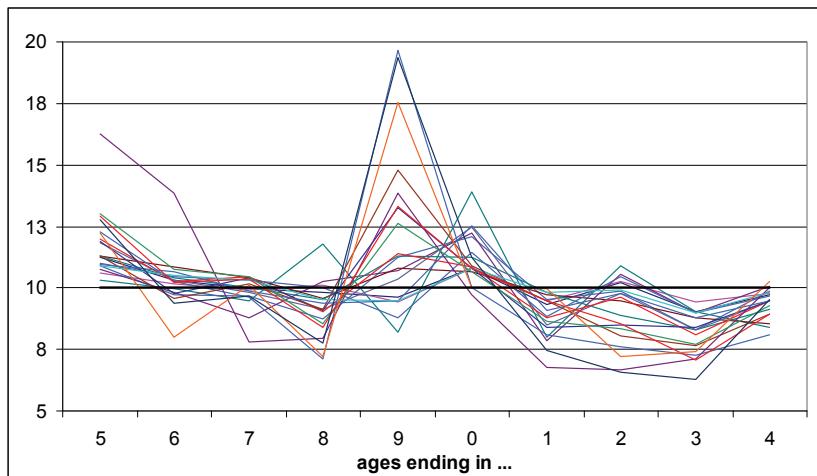

Further considerations concerning the quality of the data will be presented after we have estimated the probabilities of death and the life table, and compared infant mortality at different ages and by sex across the *Länder*.

**Figure 4:** Percent of last digit in death ages 5-94.  
*Länder of the Austrian Empire, 1852*

### 3. Life tables for ages 0-3 for the cohort born in 1851

Complete data on deaths by the nine ages marking the first three years of life are available for the years 1851-1854. Consequently, it is possible to build a life table up until the third birthday for the cohort born in 1851 by means of some approximations (Figures 5 and 6). More specifically, the *Tafeln* include:

For the first year of life:

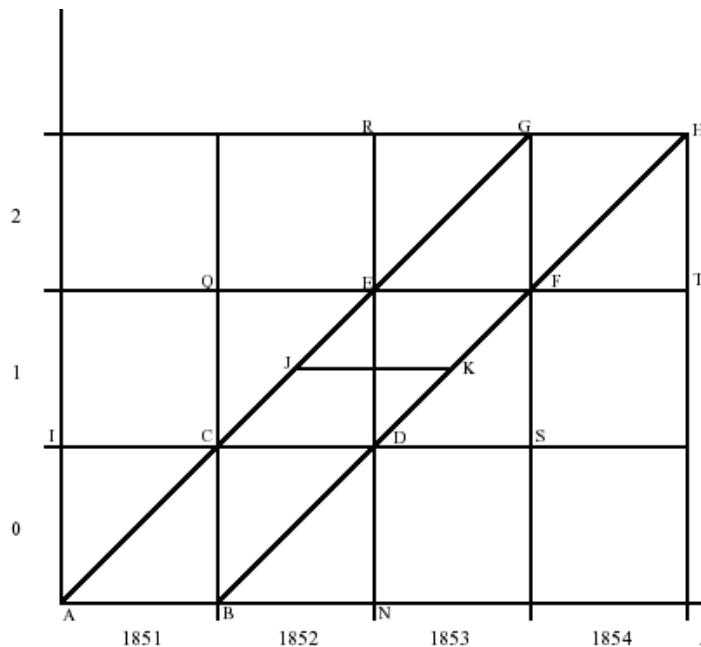

- Deaths in the first month of life in 1851 and 1852;
- Deaths in the second month of life in 1851 and 1852;
- Deaths in the third month of life in 1851 and 1852;
- Deaths in the 4<sup>th</sup>, 5<sup>th</sup> and 6<sup>th</sup> months of life in 1851 and 1852;
- Deaths in the 7<sup>th</sup>, 8<sup>th</sup> and 9<sup>th</sup> months of life in 1851 and 1852;
- Deaths in the 10<sup>th</sup>, 11<sup>th</sup> and 12<sup>th</sup> months of life in 1851 and 1852;

For the second year of life:

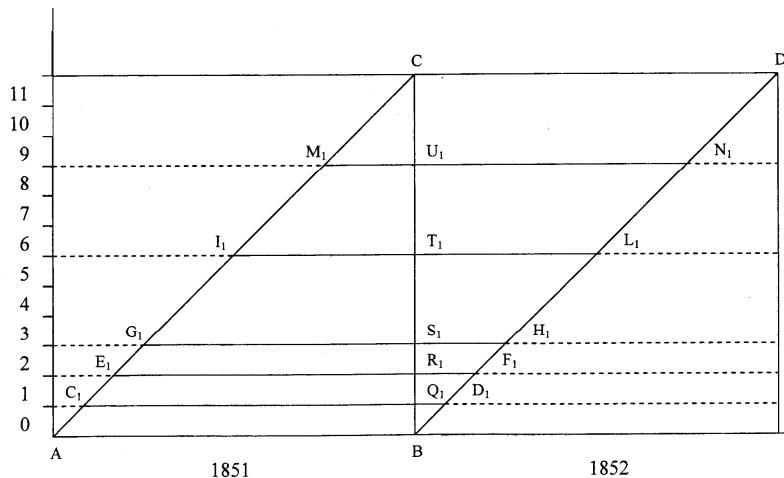

- Deaths between the 13<sup>th</sup> and 18<sup>th</sup> months of life in 1852 and 1853;
- Deaths between the 19<sup>th</sup> and 24<sup>th</sup> months of life in 1852 and 1853.

The data are not, however, organised by cohort (parallelogram in Figures 5 and 6), but rather by period (rectangles). To calculate the life table for the cohort born in 1851, deaths by year at birth and age (parallelograms) must be estimated, starting from deaths by year at death and age (rectangles).

**Figure 5:** Lexis's scheme for life tables at ages 0-3 in the *Länder* of the Austrian Empire. Birth cohort 1851

**Figure 6:** Lexis's scheme for life tables at ages 0-11 months in the *Länder* of the Austrian Empire. Birth cohort 1851

As data are detailed by month (for the first three months of life), quarterly (until the first birthday), bi-yearly until the second birthday, and annually for the third year of life, it is not too rash to suppose that deaths are equally distributed into each of these age classes. Under this hypothesis, it is a simple matter to estimate for each age the number of deaths belonging to the cohort born in 1851. The deaths during the first month for those born in 1851 are estimated as the sum of 23/24 of the deaths which occurred during the first month registered in 1851, and 1/24 of the deaths registered during the first month of 1852. In Figure 6, these two addenda are the trapezium AC<sub>1</sub>Q<sub>1</sub>B and the triangle BQ<sub>1</sub>D<sub>1</sub>, which are composed in the parallelogram AC<sub>1</sub>D<sub>1</sub>B. This method is similarly employed for the other ages, changing the proportions as follows:

*Deaths in the 2<sup>nd</sup> month of life, for those born in 1851:*

$$\begin{aligned} C_1E_1F_1D_1 = & 21/24 \times \text{Deaths in 2<sup>nd</sup> month registered in 1851} + \\ & + 3/24 \times \text{Deaths in 2<sup>nd</sup> month registered in 1852}; \end{aligned}$$

*Deaths in the 3<sup>rd</sup> month of life, for those born in 1851:*

$$\begin{aligned} E_1G_1H_1F_1 = & 19/24 \times \text{Deaths in 3<sup>rd</sup> month registered in 1851} + \\ & + 5/24 \times \text{Deaths in 3<sup>rd</sup> month registered in 1852}; \end{aligned}$$

*Deaths in the 4<sup>th</sup>, 5<sup>th</sup>, and 6<sup>th</sup> months of life, for those born in 1851:*

$$G1I1L1M1 = 45/72 \times \text{Deaths in } 4^{\text{th}}, 5^{\text{th}}, 6^{\text{th}} \text{ months registered in 1851} + \\ + 27/72 \times \text{Deaths in } 4^{\text{th}}, 5^{\text{th}}, 6^{\text{th}} \text{ month registered in 1852};$$

*Deaths in the 7<sup>th</sup>, 8<sup>th</sup>, and 9<sup>th</sup> months of life, for those born in 1851:*

$$I1M1N1L1 = 27/72 \times \text{Deaths in } 7^{\text{th}}, 8^{\text{th}}, 9^{\text{th}} \text{ months registered in 1851} + \\ + 45/72 \times \text{Deaths in } 7^{\text{th}}, 8^{\text{th}}, 9^{\text{th}} \text{ months registered in 1852};$$

*Deaths in the 10<sup>th</sup>, 11<sup>th</sup>, and 12<sup>th</sup> month of life, for those born in 1851:*

$$M1CDN1 = 9/72 \times \text{Deaths in } 10^{\text{th}}, 11^{\text{th}}, 12^{\text{th}} \text{ months registered in 1851} + \\ + 63/72 \times \text{Deaths in } 10^{\text{th}}, 11^{\text{th}}, 12^{\text{th}} \text{ months registered in 1852};$$

And in Figure 5:

*Deaths in the 13<sup>th</sup>-18<sup>th</sup> month of life, for those born in 1851:*

$$CJKD = 108/144 \times \text{Deaths in } 13^{\text{th}}\text{-}18^{\text{th}} \text{ months registered in 1852} + \\ + 36/144 \times \text{Deaths in } 13^{\text{th}}\text{-}18^{\text{th}} \text{ months registered in 1853};$$

*Deaths in the 19<sup>th</sup>-24<sup>th</sup> month of life, for those born in 1851:*

$$JEFK = 36/144 \times \text{Deaths in } 19^{\text{th}}\text{-}24^{\text{th}} \text{ months registered in 1852} + \\ + 108/144 \times \text{Deaths in } 19^{\text{th}}\text{-}24^{\text{th}} \text{ months registered in 1853};$$

*Deaths in the third year of life, for those born in 1851:*

$$EGHF = 1/2 \times \text{Deaths in } 3^{\text{rd}} \text{ year registered in 1853} + \\ + 1/2 \times \text{Deaths in } 3^{\text{rd}} \text{ year registered in 1854}$$

The live births in 1851 still surviving at each exact age  $x$  ( $S_x$ ) are calculated as:  
 $S_{x+1}=S_x-D_x$ . For the first month of life (Figure 5):  $C_1D_1=AB-AC_1D_1B$ , for the second month:  $E_1F_1=C_1D_1-C_1E_1F_1D_1$  etc.

The probabilities of death are calculated as  $q_x=D_x/S_x$ .

For the first month of life (Figure 6):  $q_{1^{\text{st}} \text{ month}}=q_0=(AC_1D_1B)/AB$ ; for the second month:  $q_{2^{\text{nd}} \text{ month}}=q_1=(AC_1D_1B)/AB$ , etc.

Some distortions could come from migrations, as some children could be born in one region, and die in another. However, each *Land* is large enough to suggest that this problem should not be too important.

Table 7 contains these probabilities, indicated in months:  $nq_x$  is thus the probability for a survivor at exactly  $x$  months of dying before having turned  $x+n$  months. Using this series of probabilities (Table 7), we calculate the life table for the first three years of life, starting from  $I_0=100,000$ : *deaths*  $d_x=(l_x \times q_x)$  and *survivals*  $(l_{x+1})=l_x-d_x$  (Tables 9

and 10). Table 8 contains the index numbers of death probability  $q_x$  presented in Table 7 (total Austrian Empire=100). Finally, Table 11 reports annual probabilities  $q_0$ ,  $q_1$ ,  $q_2$ , and the three years of probabilities  ${}^3q_0$ .

Given that the population numbers in some *Länder* are relatively low, death probabilities (and, consequently, all of the parameters of the life table) are influenced by random variation. To address this issue, we calculated for the less populous *Länder* the confidence intervals at 5% for the death probabilities  $q_x$ :

$$q_x \pm 1.96 \sqrt{\frac{q_x(1-q_x)}{N_x}}$$

where  $N_x$  is the number of people exposed to death, i.e., the denominator of  $q_x$  (Table 12). Even in the least populated region (*Salzburg*), the confidence interval for  $q_0$  (first month of life) is large enough to allow for reasonable comparisons between *Länder*. Several issues arise for the ages which follow, as the intervals widen in a relative measure. However, for *Kärnten* the confidence intervals for all ages are narrow enough. Consequently, for the other *Länder*, the death probabilities at each age are only marginally influenced by the random variation.

	Intervals	$\pm 7.1$	$\pm 3.4$	$\pm 3.2$	$\pm 4.3$	$\pm 3.6$	$\pm 3.3$	$\pm 3.8$	$\pm 2.6$	$\pm 3.6$

A first look at the differences between regions suggests that some information may have been under-registered. In five of the regions, the probability of dying during the first month is lower than 100%. In the regions of *Krain* and *Krakau*, this relatively low level corresponds to low mortality during the two months which follow, whereas in *Bukovina*, *Galizien*, and *Siebenbürgen*, this does not occur (Table 7). Consequently, in these three *Länder* neonatal mortality may have been under-registered.

We now turn to the results in Table 7, where the probabilities  $nq_x$  are expressed in months, by age intervals of different size  $n$ . After three months of life, in some *Länder* the probability of death at several ages is higher than the analogous probability at the preceding age. For example,  ${}_3q_6$  is greater than  ${}_3q_3$  only in the *Länder Görz, Gradisca und Istrien*, and *Triest sammt Gebiet*; but  ${}_3q_9$  is higher than  ${}_3q_6$  in many central-eastern *Länder* (Table 13). Similarly,  ${}_6q_{12}$  is higher than  ${}_6q_6$  in only one *Land*, (*Venedig*), but  ${}_6q_{18}$  is higher than  ${}_6q_{12}$  in six *Länder* (*Galizien*, *Bukovina*, *Ungern*, *Serbische Wojwodschaft und Temeser Banat*, *Siebenbürgen*, and *Militärgränze*). Although such situations are not impossible, they are rather rare. For example, among the English population between 1580 and 1837 (Wrigley et al. 1997:226), in 11 periods of about 25 years each, the ratio  ${}_3q_6 / {}_3q_3$  is (only slightly) greater than one only once, and the ratio  ${}_3q_9 / {}_3q_6$  only twice. These results strongly suggest that great caution should be used when considering some of our results, in particular those relative to the probability that a survivor at nine months will die by 12 months of life, which, in fact, often appears to be higher than the same probability of the preceding trimester. This could be a consequence of possible attractions to terminal numbers, as many of the *Länder* characterised by this situation are precisely those in which an unusual attraction to the number 9 is seen in the annual life table (Table 6 and Figure 4).

A strong suspicion that probabilities of death at 9-12 months had been overestimated in several *Länder* motivated us to join this age class with the two contiguous classes, and hence to jointly calculate the probabilities of death at 6-18 months (Table 14). The greater regularity of these results (only one *Land* with a higher probability than that of the preceding age class remains) leads us to conclude that the interval of 9-12 months attracts, in part, that of 6-9 months, and, to a lesser extent, that of 12-18 months. However, a somewhat suspect situation still remains – in the *Länder* with anomalous attractions to numbers – due to the probability of death at ages 18-24 months, which in some cases was found to be higher than that of the preceding semester. The entity of possible error is, however, much smaller than in the preceding case.

Taking all of these observations into consideration, in order to succinctly compare mortality during the first three years of life in the *Länder*, while simultaneously avoiding problems linked to age-heaping, we use four intervals (Table 14):

- the first month of life ( $q_0$ );
- the following five months ( ${}_5q_1$ ), given that the territorial series of probabilities  $q_1, q_2, {}_3q_3$  are highly correlated;
- the 12 months which run from the 7<sup>th</sup> to the 18<sup>th</sup> months of life ( ${}_{12}q_6$ );
- the 18 months which run from the 19<sup>th</sup> to the 36<sup>th</sup> months of life ( ${}_{18}q_{18}$ ).

Figures 7 through 11 show the geography of *Länder* with elevated, intermediate, and low levels of mortality for the four classes defined above, and for the entire class up to three years of age, highlighting an often evident territorial contiguity of regions with similar levels.

#### 4. A brief discussion of territorial differences

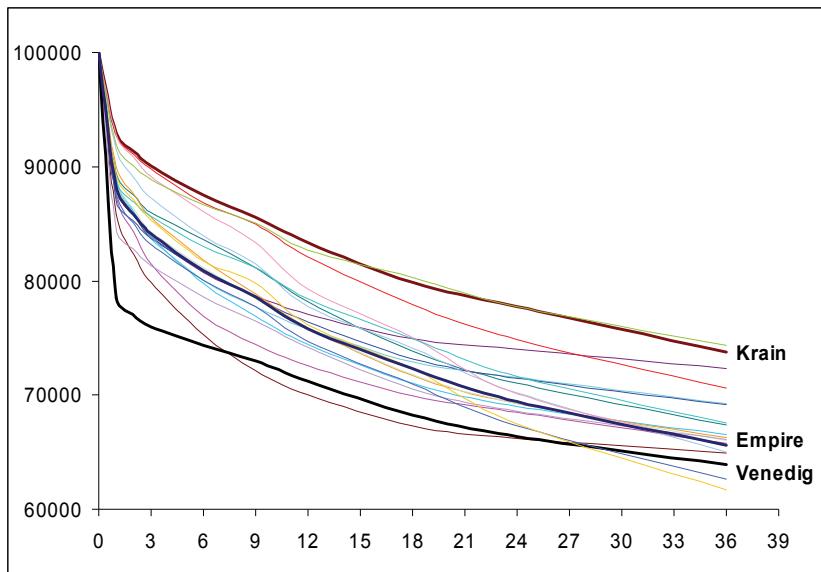

The main aim of this article is methodological: to test the quality of detailed data published in the mid-19<sup>th</sup> century *Tafeln* on infant mortality in the Austrian Empire *Länder*. In the previous section, we suggested that the quality of the data is relatively good, with the exception of information on stillbirths and that on age at death in some *Länder*. In these final sections, we conclude by briefly discussing several substantive topics, emphasising geographical aspects.

A complete comparison of the *Länder* must take into account the larger demographic history of each *Land* (or at least infant mortality). The *Tafeln* may be very useful for describing the long-term processes of infant mortality, as they cover the long time-span of 1829-1871. These statistical tables also allow scholars to cross infant mortality with several specific characteristics of the *Länder*, such as education, urbanization, religion, economic situation, etc. The published life tables presented here thus represent only a snapshot of a potentially much broader picture.

In addition, data of this type (when sufficient quality exists) allow for regional comparisons of an Empire that was home to 35 million people—an uncommon situation during the *ancien régime*. Our results provide support for Livi Bacci's argument cited at the beginning of this article: territorial variability is notable, and standard deviations are large and similar for each series of death probabilities. Moreover, in some cases, bordering *Länder* are characterised by opposite levels (see for example, the differences among the *Länder* in actual Austria (the first five rows of Table 8), as already emphasised by other authors (Prioux 1993; Kytir, Köck, and Münz 1995; Viazza 1997).

Overall mortality in the first three years of life is quite variable, as has already been observed (Figures 11 and 12). High levels, or those of 350% and beyond, appear in the eastern (*Galizien*, *Bukovina*, *Ungern*), southern (*Militärgränze*), and western (*Venedig*, *Salzburg*) regions. Nonetheless, the distribution by age at death across the first three years of life in the different regions is quite diverse (Figures 7-10). Mortality is rather high in the first month throughout a vast western and central area, which reaches as far as *Ungern*. Between the second and the sixth months, the probability of death is instead higher in the central regions. Indeed, a closer look at Figure 8 shows great continuity, but also a certain gradient towards the more peripheral areas, particularly the more southern regions (with the exception of *Militärgränze*). For the age interval between the 7<sup>th</sup> and the 18<sup>th</sup> months (Figure 9), we see almost the inverse: low mortality in the central regions and high mortality in the northern (*Mähren*, *Schlesien*, *Galizien*, *Bukovina*) and southern (*Militärgränze*, *Istrien*) peripheral regions. Finally, at over 18 months (Figure 10), mortality is higher in the eastern and southern *Länder*, and lower in the central and northern regions.

**Figure 12:** Life tables for the first 36 months of life. Cohort born in 1851 in the *Länder* of the Austrian Empire. Variability of the survival function  $\bar{l}_x$

## 5. Was there discrimination against female children?

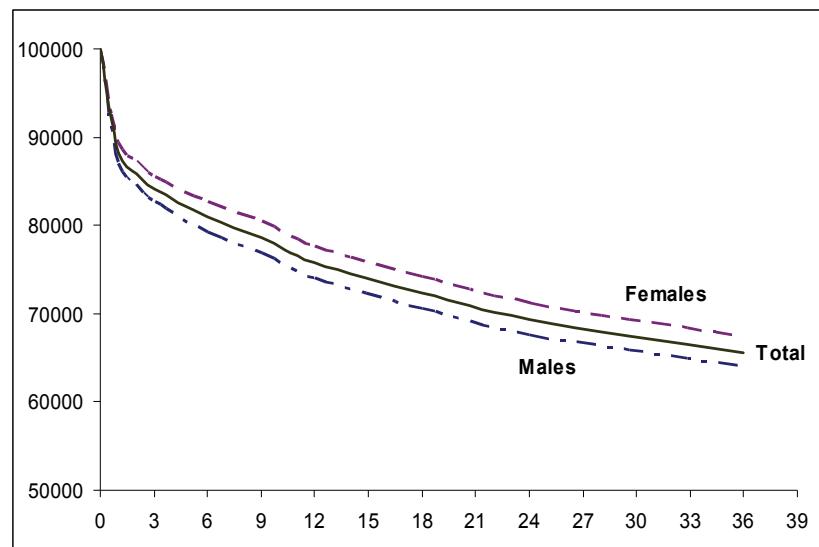

Differences by sex are not widely apparent for the Empire as a whole (Tables 15 and 16 and Figure 13). Males are penalized at every age, although this difference declines after the ninth month of life. On the other hand, the Empire's mean values hide deep regional differences. Consider, for example, four "extreme" situations. In *Steiermark*, the generally low level of infant mortality is mainly due to the high survival rates of females. Similarly, in *Salzburg*, low mortality after the ninth month is caused by the high survival rates of females. In *Bukovina*, on the other hand, infant mortality is very high after the ninth month of life due to very high female mortality. Finally, in *Venedig*, very high neonatal mortality is similarly due to the lack of female under-mortality.

**Table 15:** Life tables for the first 36 months of life. Cohort born in 1851 in the *Länder* of the Austrian Empire. Death probability ( $1,000 \times nq_x$ ) for males and females

We further investigate these aspects through use of Bourgeois-Pichat's (1951) decomposition method between exogenous and endogenous infant mortality components, extending this method to the analysis of deaths up until the third birthday separately for males and females. If the sex ratio for endogenous mortality had been more favourable to female infants relative to the ratio observed for exogenous mortality, then there may have been an under-registration of neonatal female mortality.

Generally, for all of the Empire, mortality up until three years of age (344‰) is decomposed between endogenous mortality (87‰, equal to 25%) and exogenous mortality (257‰, equal to 75%). The ratio between female and male exogenous mortality is much less variable than the analogous endogenous ratio, and in only a few cases does exogenous female mortality resemble that of male mortality. These cases include *Salzburg*, *Tirol und Vorarlberg*, *Serbische*, and *Militärgränze*; while *Venedig*, and above all *Bukovina*, are the only *Länder* in which exogenous female mortality surpasses male mortality. With regard to the lowest ratio levels, only *Steiermark* and *Krain* have values that fall below 0.9, but these two regions are also among the *Länder* with the lowest mortality rates between the ages of 0-2. Figure 14 and Table 17 show that the *Länder* “suspected” of under-registering endogenous female mortality are *Krain*, *Krakau*, *Bukovina*, and *Galizien*, which coincide quite closely with – when observing the probabilities of death in the first three years of life independently of sex – the areas in which we noted that neonatal mortality seemed too low with respect to the months which followed (see above).

(\*) Oesterreich unter der Enns, Dalmatien, and Kroatien und Slavonien not included.

Further study of these gender differences can be pursued through use of a technique proposed by Hill and Upchurch (1995). These authors built a kind of standard difference between female and male infant mortality, which varies with mortality rates. They observed the relationship between male mortality up to five years of age, and the ratio between female and male mortality at ages 0, 1-4, and 0-4. Interpolating the three clouds of points with a curve and smoothing, Hill and Upchurch obtained the ratio between the probabilities of female and male death expected for the three ages, given a certain level of male mortality at ages 0-4. To carry out their estimates, they used data extracted from the 1820-1964 life tables of several Central European countries and New

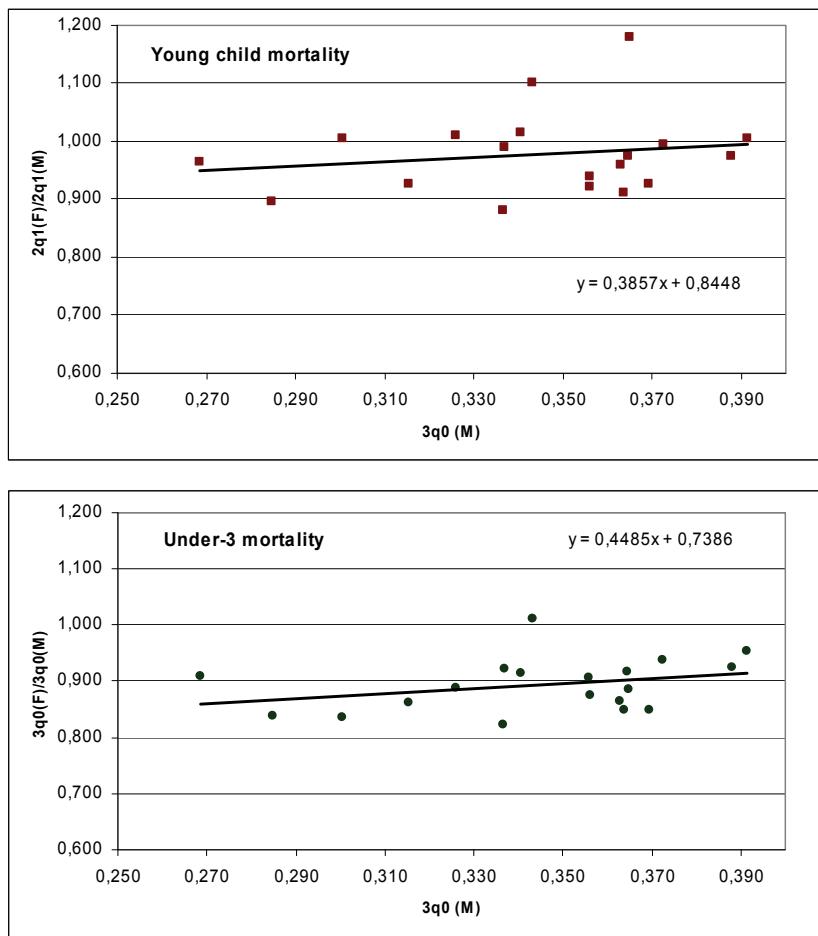

Zealand (all tables considered to be of high quality). They compared their expected results with those actually found in recent investigations conducted in different developing countries, building a measure of discrimination disfavouring female children; or, to be more exact, as clarified by the authors, the actual discrimination in several developing countries with respect to the discrimination in countries more than a century ago, which were chosen to build the tables (Hill and Upchurch 1995:132)

Our data allow us to build probabilities of death only up until the third birthday, and thus a direct comparison with Hill and Upchurch's standard tables is not possible. On the other hand, it is feasible to construct the same relationships observed by the two authors using data on male mortality at ages 0-2 in the 19 *Länder* for which data are available (Table 18 and Figure 15). The index of discrimination is calculated as the difference between the actual ratio  $q_F/q_M$ , and the theoretical ratio if gender discrimination were the mid-19<sup>th</sup>-century Austrian Empire's "average," as expressed by the interpolating line.

\*) The actual ratio of female to male mortality minus the expected ratio according to the average situation of the Empire.

A comparison of our results with those obtained by Hill and Upchurch for developing countries where significant discrimination against female children exists today allows us to surmise that, among the Austrian Empire *Länder*, female infants were not particularly penalised (Table 18). The differences with a positive sign – indicating higher female mortality than expected – are relatively low, with the exception of *Bukovina* (which for all ages has higher differences), *Siebenbürgen* (which has somewhat notable differences in the first year of life), and *Salzburg* (which has a large difference only for the age classes 1-2; although the results could be skewed by small numbers). Large differences with a negative sign could instead indicate less female mortality. These cases are, however, rare, and are limited to *Steiermark*, *Mähren*, and perhaps *Oesterreich ob der Enns*.

The results illustrated thus far could be disproved in part if an under-registering of precocious female deaths could be shown to have taken place (due, for example, to exposure or to abandonment in inappropriate places) precisely in the areas where female infants were most neglected. Our impression is, however, that this problem – if present – was relatively contained. In the first place, even when taking into account the “suspected” exceptions mentioned above, the dispersion of the points around the interpolating line is not greater than that observed for countries whose statistics have been judged to be very reliable (cfr. Figure 15 and Hill and Upchurch’s Figure 1 (Hill and Upchurch 1995:131)). In the second place, the sign of the index for the first year of life is almost always the same as that observed in the following two-year period. On the contrary, in the case of significant under-registration of neonatal female deaths, we should have found sign reversals precisely in the regions – like *Bukovina* – where female infants were most neglected. Finally, the indicators in Table 18 delineate – with few exceptions – two areas: the centre-north (with a negative sign) and the south-east (with a positive sign). This territorial regularity could indicate different levels of gender discrimination.

We conclude this section with a brief comment on mortality differences by legitimacy. During the first period of life, mainly the first year, mortality is higher for illegitimate births in all of the *Länder*. Table 19 and Figure 16 show that the difference in survival between illegitimate and legitimate infants is not lower where illegitimacy is higher. The story is likely more complicated, and related to local peculiarities and nuptiality patterns, as shown for Austria by Priox (1993).

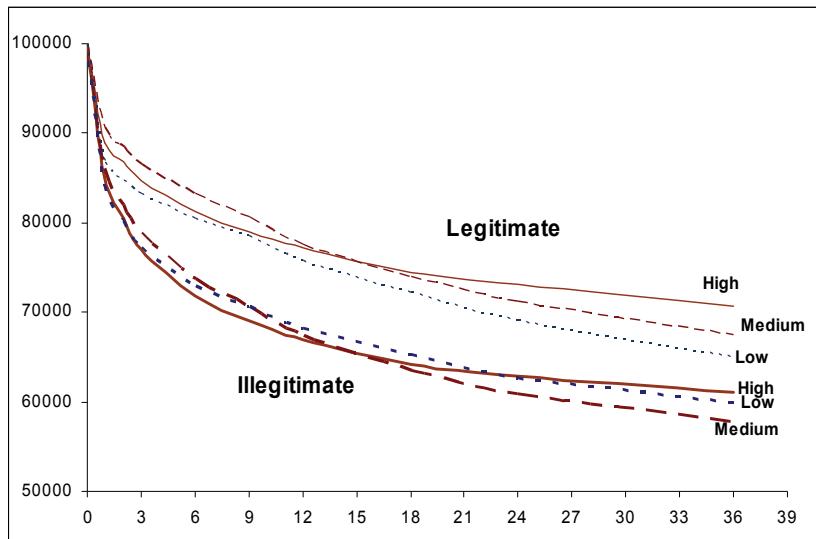

**Table 19: Life tables for the first 36 months of life. Cohort born in 1851 in the Länder of the Austrian Empire. Death probability  $1000 \times nq_x$  for legitimate and illegitimate births. Länder grouped by level of illegitimacy (\*)**

(\*) High level of illegitimacy (20% or higher during 1851-54): Oesterreich ob der Enns, Salzburg, Steiermark, and Karnthen.  
 Medium (5-20%): Krain, Görz Gradisca und Istrien Triest sammt Gebiet, Tirol und Vorarlberg, Böhmen, Mähren, Schlesien, Krakau sammt Gebiet, Galizien, and Bukovina.

Low (5% or lower): Lombardie, Venedig, Ungern, Serbische Woiwodschaft und Temeser Banat, Siebenburgen, and Militärgrazze.

**Figure 16:** Life tables for the first 36 months of life. Cohort born in 1851 in the *Länder* of the Austrian Empire. Survival function  $I_x$  for legitimate and illegitimate births by level of illegitimacy (\*)

(\*) High level of illegitimacy (20% or higher during 1851-54): Oesterreich ob der Enns, Salzburg, Steiermark, and Kärnthen.

Medium (5-20%): Krain, Görz Gradisca und Istrien Triest sammt Gebiet, Tirol und Vorarlberg, Böhmen, Mähren, Schlesien, Krakau sammt Gebiet, Galizien, and Bukovina.

Low (5% or lower): Lombardie, Venedig, Ungern, Serbische Woiwodschaft und Temeser Banat, Siebenbürgen, and Militärgrenze.

## 6. Conclusions

The *Tafeln zur Statistik der Österreichischen Monarchie* are a valuable source of data. These mid-19<sup>th</sup>-century tables represent an immense achievement on the part of a powerful political machine (which, by the 1850s, had been running strong for 20 years), involving all of the administrative apparatus governing the Austrian Empire's 35 million inhabitants. Among the types of information gathered, that on infant births and deaths is of considerable importance, not least for the particular attention paid to detail, which was rarely found even in the decades that followed. This article demonstrates that – with several exceptions and some basic cautions – the material on infant mortality

published in the *Tafeln* around 1850 guarantees reliable comparability between the Empire's *Länder*. The greatest obstacles are the likely under-registration of neonatal deaths – especially of females – in several north-eastern *Länder*, particularly *Bukovina* and *Galizien*, and the rather unusual age-heaping, mainly with regard to ages ending in 9. In addition, data on stillbirths are difficult to use because the criteria employed to collect such information not only differed from those used today, but they also varied from area to area. Apart from these issues, the data are of good quality, in that sex, age at death, and legitimacy were all recorded with accuracy.

This article, which is of a methodological nature, provides only a few examples of potential analyses which might be carried out using such rich and detailed territorial data. The geography of mortality in the first three years of life varied by age, but according to intervals that differ from those usually employed when studying early mortality. Four ages can be identified (first month, months 1-5, months 6-17, and months 18-35) with a geography of differing mortality. In all likelihood, in each of these age groups, the reasons for the mortality differences between *Länder* were diverse. Life tables differentiated by sex and more sophisticated life models (those proposed by Bourgeois-Pichat in 1951 and by Hill and Upchurch in 1995) suggest that, in the south-eastern area of the Empire, female children were more heavily penalized than in the north-western regions, albeit to a much lesser extent than that observed in several of today's poorer countries. Finally, the diffusion of births outside of wedlock varied significantly: levels were quite high in the heart of today's Austria; medium levels were seen in the other Austrian regions, in the transalpine areas bordering Austria, and in the regions west of the Empire; and very low levels were found in the southern *Länder*. The direct relationship between mortality and illegitimacy were found to persist everywhere, regardless of the level of illegitimacy.

Validation of the quality of infant mortality data contained in the *Tafeln* around the mid-19<sup>th</sup> century opens up interesting directions for future research. First, it will be possible to construct long series of infant mortality indicators using the complete *Tafeln* data from 1829 to 1871, and to connect these series to data available for the following periods. In addition, the previous years may be taken into account, as Volume II of the *Tafeln* of 1829, Table 6.1 contains births and deaths (including infant deaths) for 1819-1828: year-by-year for the Empire without Hungary, and totals for the 10-year period for its provinces. Second, in-depth investigations of the underlying reasons for territorial differences could be pursued by linking infant mortality indicators with other quantitative variables (education, religion, social stratification, etc. – many of which are obtainable from the *Tafeln* themselves). Third, the good quality of the aggregated data should encourage the collection of elementary or intermediate data (by districts or provinces) which – once aggregated – form the basis of the data on infant births and deaths published in the *Tafeln*. This project is currently underway for the region of

*Venedig*, and thus far has provided encouraging results (Clerici 1991; Dalla-Zuanna and Rosina 2008). Finally, indicators on infant mortality could be used to reconstruct the different demographic regimes that existed among the Austrian Empire *Länder* during the 19<sup>th</sup> century, and to observe the first signs of the Demographic Transition.
